Multiequilibria analysis for a class of collective decision-making networked systems

Angela Fontan and Claudio Altafini

Abstract—The models of collective decision-making considered in this paper are nonlinear interconnected cooperative systems with saturating interactions. These systems encode the possible outcomes of a decision process into different steady states of the dynamics. In particular, they are characterized by two main attractors in the positive and negative orthant, representing two choices of agreement among the agents, associated to the Perron-Frobenius eigenvector of the system. In this paper we give conditions for the appearance of other equilibria of mixed sign. The conditions are inspired by Perron-Frobenius theory and are related to the algebraic connectivity of the network. We also show how all these equilibria must be contained in a solid disk of radius given by the norm of the equilibrium point which is located in the positive orthant.

Index Terms—Collective decision-making; nonlinear cooperative systems; multiple equilibria; Perron-Frobenius theorem; algebraic connectivity.

I. INTRODUCTION

NONLINEAR interconnected systems are used in broadly different contexts to describe the collective dynamical behavior of an ensemble of “agents” interacting with each other in a non-centralized manner. They are used for instance to represent collective decision-making by animal groups [1], [2], [3], formation of opinion in social communities [4], [5], dynamics of a gene regulatory network [6], or neural networks [7]. Such models often share similar features, like the fact of using first order dynamics at a node and sigmoidal saturation-like functions to describe the interactions among the nodes [8], [7], [9], [10]. The latter functional form is instrumental to avoid diverging dynamics. The price to pay for having an effectively “bounded” dynamics is however the appearance of complex dynamical phenomena such as periodic orbits or multiple equilibrium points, which complicate considerably the behavior of the system and its understanding. While (stable) periodic orbits can be ruled out by choosing functional forms which are, beside saturated, also monotone [11], [12], it is in general more difficult to deal with multiple equilibria. These are often a necessary feature of a model, like for instance, when describing bistability in a biological system. In the literature on agent-based animal groups for instance, the collective decision is typically a selection between two different attractors [1], [2], [3]. A scenario that occurs often is that of a finite number of attractors, each with its own basin of attraction, encoding the possible outcomes of the collective decision-making process. This is for instance the model of choice of several classes of neural networks, like the so-called Hopfield [8] or Cohen-Grossberg [13] neural networks. When a neural network is interpreted as an associative memory storage device or is used for pattern recognition, the presence of a high number of stable equilibria increases the storage capacity of the network. The multistability of neural networks has in fact been extensively investigated in recent years [14], [15], [16], [17], [18], see also [19] for an overview.

The model adopted in this paper is described in [1], [20], [21]. All interactions are “activatory”, i.e., the adjacency matrix is nonnegative. In addition, it is symmetric or diagonally symmetrizable and irreducible. The model has a Laplacian-like structure at the origin and monotone saturating nonlinearities to represent the interaction terms. The amplitude of the interaction part is modulated by a scalar parameter, interpretable as the strength of the social commitment of the agents, and playing the role of bifurcation parameter. When the parameter is small, the origin is globally stable, as can be easily deduced by (global) diagonal dominance. The interesting dynamics happens when the parameter passes a bifurcation threshold: the origin becomes unstable, and two locally stable equilibria, one positive, the other negative, are created. This is the behavior described in [1]. The bifurcation analysis of [1], however, captures what happens only in a neighborhood of the bifurcation point. Moving away from the bifurcation, all is known is that the positive and negative orthants remain invariant sets for the dynamics, and each keeps having a single asymptotically stable equilibrium point, see [20], [21]. What happens in the remaining orthants is unknown and its investigation is the scope of this paper.

It is useful to look at the neural network literature (in our knowledge the only field that has studied the multiequilibria problem is a systematic way for such interconnected systems). It is known since [8] that for neural networks with connections that are symmetric, monotone increasing and sigmoidal, the equations of motion always lead to convergence to stable steady states. The number of such equilibria is shown to grow exponentially with the number $n$ of “neurons” for various specific models [14], [15], [16], [17]. In order to count equilibria, often in these papers one has to resort to nondecreasing piecewise linear functions to describe the saturations, and to obtain algebraic conditions on the equilibria by looking at the corners and at the constant slopes. The existence of the equilibria is also checked through Brouwer fixed-point arguments. None of these methods apply in our case.

The consequence is that in order to investigate the presence of multiple equilibria in our system we have to take a com-

Work supported in part by a grant from the Swedish Research Council (grant n. 2015-04390). A preliminary version of this manuscript was presented at the 56th IEEE Conf. on Decision and Control, 2017.

A. Fontan and C. Altafini are with the Division of Automatic Control, Department of Electrical Engineering, Linköping University, SE-58183 Linköping, Sweden, E-mail: {angela.fontan, claudio.altafini}@liu.se
completely different approach. Since the adjacency matrix of our network is nonnegative, we can use Perron-Frobenius theorem and geometrical considerations that follow from it. The main result of the paper is a necessary and sufficient condition for existence of equilibria outside $\mathbb{R}^+_n/\mathbb{R}^n$, formulated in terms of the second largest positive eigenvalue of the adjacency matrix. Roughly speaking, this condition says that the interval of values of the bifurcation parameter in which no mixed-sign equilibrium can appear is determined by the algebraic connectivity of the Laplacian of the system [22], [23], [24].

While our necessary condition is always valid, our proof of sufficiency is based on singularity analysis of bifurcations [25], and is valid under the assumption that the algebraic connectivity has multiplicity one, condition which is generically true [26]. For consensus problems, the role of the algebraic connectivity is well-known: the bigger is the gap between $0$ (the least eigenvalue of the Laplacian) and the algebraic connectivity, the more robust the consensus is to model uncertainties, parameter variations, node or link failures, etc. [23]. In the present context, the spectral gap in the Laplacian (or, more properly, in the adjacency matrix), represents the range of values of social commitment of the agents which leads to a choice between two alternative agreement solutions, with a guaranteed global convergence. Beyond the value represented by the algebraic connectivity, however, the system bifurcates again, and a number of (stable and unstable) mixed-sign equilibria appears quickly, destroying the global convergence to the agreement manifold in which the two alternative attractors live. Although we can investigate these extra equilibria only numerically, it is nevertheless possible to compute exactly the region in which they must be. The second analytical result of the paper is in fact that for all values of the bifurcation parameter the mixed-sign equilibria have to have norm less than the norm of the equilibrium in $\mathbb{R}^n$. In other words, all the equilibria of the system must be contained in a ball centered in the origin of $\mathbb{R}^n$ and of radius equal to the norm of the positive equilibrium point. Our numerical analysis shows that stable equilibria tend to localize towards the boundary of this ball, while those near the origin tend to have Jacobians with several positive eigenvalues, and a similar number of positive and negative components.

The rest of this work is organized as follows. Preliminary material is introduced in Section II. The main results are stated in Sections III and IV; the first section provides the necessary and sufficient condition for the existence of mixed-sign equilibria, while the second describes the region in which they must be contained. Section V finally provides a numerical analysis of the equilibria.

A preliminary version of this paper appears in [27]. It contains only the necessary condition discussed in Section III, and lacks the proof of most of the results.

II. PRELIMINARIES

A. Concave and convex functions

Let $\mathcal{U} \subseteq \mathbb{R}^n$ be a convex set. A function $f : \mathcal{U} \to \mathbb{R}$ is convex if for all $x_1, x_2 \in \mathcal{U}$ and $\theta$ with $0 \leq \theta \leq 1$, we have

$$f(\theta x_1 + (1-\theta)x_2) \leq \theta f(x_1) + (1-\theta)f(x_2).$$

It is strictly convex if strictly inequality holds in (1) whenever $x_1 \neq x_2$ and $0 < \theta < 1$. We say $f$ is concave if $-f$ is convex, and strictly concave if $-f$ is strictly convex. Suppose $f : \mathcal{U} \to \mathbb{R}$ is differentiable. Then $f$ is convex if and only if

$$f(x_1) - f(x_2) \geq \nabla f(x_2) \cdot (x_1 - x_2)$$

for all $x_1, x_2 \in \mathcal{U}$. It is strictly convex if and only if strict inequality holds in (2) for all $x_1 \neq x_2$ and $x_1, x_2 \in \mathcal{U}$.

B. Nonnegative matrices and Perron-Frobenius

The set of all $\lambda \in \mathbb{C}$ that are eigenvalues of $A \in \mathbb{R}^{n \times n}$ is called the spectrum of $A$ and is denoted by $\Lambda(A)$. The spectral radius of $A$ is the nonnegative real number $\rho(A) = \max \{ |\lambda| : \lambda \in \Lambda(A) \}$.

A matrix $B \in \mathbb{R}^{n \times n}$ is said to be similar to a matrix $A \in \mathbb{R}^{n \times n}$, abbreviated $B \sim A$, if there exists a nonsingular matrix $S \in \mathbb{R}^{n \times n}$ such that $B = S^{-1}AS$. If $A$ and $B$ are similar, then they have the same eigenvalues, counting multiplicity.

A matrix $A \in \mathbb{R}^{n \times n}$ is said to be reducible if either $n = 1$ and $A = 0$ or if $n \geq 2$, there is a permutation matrix $P \in \mathbb{R}^{n \times n}$ and some integer $r$ with $1 \leq r \leq n - 1$ such that $P^TAP = \begin{bmatrix} B & C \\ 0 & D \end{bmatrix}$ where $B \in \mathbb{R}^{r \times r}, C \in \mathbb{R}^{r \times (n-r)}, D \in \mathbb{R}^{(n-r) \times (n-r)}$. A matrix $A \in \mathbb{R}^{n \times n}$ is said to be irreducible if it is not reducible.

The matrix $A = \begin{bmatrix} a_{ij} \end{bmatrix} \in \mathbb{R}^{n \times n}$ is said to be diagonally dominant if $|a_{ii}| \geq \sum_{j \neq i} |a_{ij}|$ for all $i$ and $a_{ii} > \sum_{j \neq i} |a_{ij}|$ for all $i$. If $A$ is strictly diagonally dominant if $|a_{ii}| > \sum_{j \neq i} |a_{ij}|$ for all $i$.

Theorem 1 ([28], Theorem 6.1.10) Let $A \in \mathbb{R}^{n \times n}$ be strictly diagonally dominant. Then $A$ is nonsingular. If $a_{ii} > 0$ for all $i = 1, \ldots, n$, then every eigenvalue of $A$ has positive real part. If $A$ is symmetric and $a_{ii} > 0$ for all $i = 1, \ldots, n$, then $A$ is positive definite.

Theorem 2 (Perron-Frobenius, [29] Theorem 1.4) If $A \in \mathbb{R}^{n \times n}$ is irreducible and nonnegative then $\rho(A)$ is a real, positive, algebraically simple eigenvalue of $A$, of right (left) eigenvector $v > 0$ ($w > 0$). Furthermore, for every eigenvalue $\lambda \in \Lambda(A)$ such that $\lambda \neq \rho(A)$ it is $|\lambda| < \rho(A)$ and the corresponding eigenvector $v_\lambda$ cannot be nonnegative.

Corollary 1 (Perron-Frobenius) If $A \in \mathbb{R}^{n \times n}$ is irreducible and nonnegative then either

$$\rho(A) = \sum_{j=1}^n a_{ij}, \quad \forall i = 1, \ldots, n$$

or

$$\min_i \left( \sum_{j=1}^n a_{ij} \right) \leq \rho(A) \leq \max_i \left( \sum_{j=1}^n a_{ij} \right).$$

C. Symmetric, symmetrizable and congruent matrices

Let $A \in \mathbb{R}^{n \times n}$ be symmetric. Then all the eigenvalues of $A$ are real and $S^TAS$ is symmetric for all $S \in \mathbb{R}^{n \times n}$.

A matrix $A \in \mathbb{R}^{n \times n}$ is (diagonally) symmetrizable if $DA$ is symmetric for some diagonal matrix $D$ with positive diagonal
entries. The matrix $DA$ is called symmetrization of $A$ and the matrix $D$ is called symmetrizer of $A$ [30], [31], [32]. The eigenvalues of a symmetrizable matrix are real. $A \in \mathbb{R}^{n \times n}$ is symmetrizable if and only if it is sign symmetric, i.e. $a_{ij} = a_{ji} = 0$ or $a_{ij} \cdot a_{ji} > 0$, $\forall i \neq j$, and $a_{i1} a_{j1} a_{i2} a_{j2} \ldots a_{ik} a_{jk} = a_{j1} a_{i1} a_{j2} a_{i2} \ldots a_{jk} a_{ik}$ for all $i_1, \ldots, i_k$. A matrix $B \in \mathbb{R}^{n \times n}$ is said to be congruent to the matrix $A \in \mathbb{R}^{n \times n}$ if there exists a nonsingular matrix $S$ such that $B = SAS^T$.

**Theorem 3 (Ostrowski, Theorem 4.5.9 in [28])** Let $A, S \in \mathbb{R}^{n \times n}$ with $A$ symmetric and $S$ nonsingular. Let the eigenvalues of $A, SAS^T$ and $SS^T$ be arranged in nondecreasing order. For each $k = 1, \ldots, n$, there exists a positive real number $\theta_k$ such that $\lambda_1(SS^T) \leq \theta_k \leq \lambda_n(SS^T)$ and $\lambda_k(SAS^T) = \theta_k \lambda_k(A)$.

**D. Cooperative systems**

Consider the system

$$\dot{x} = f(x), \quad x(0) = x_0$$

(5)

where $f$ is a continuously differentiable function defined on a convex, open set $U \subset \mathbb{R}^n$. We write $x(t, x_0)$ for the forward solution of (5) with initial condition $x_0 \in \mathbb{R}^n$ at $t = 0$.

The set $K$ given by $K = \{ x \in \mathbb{R}^n : k_i x_i \geq 0, k_i \in \{\pm 1\}, i = 1, \ldots, n \}$ is an orthant in $\mathbb{R}^n$. $K$ is a cone in $\mathbb{R}^n$ and it generates a partial ordering “$\preceq_K$”, i.e. $x \preceq_K y$ iff $y - x \in K$. The subscript “$K$” will be dropped in case $K = \mathbb{R}^n_+$, the nonnegative orthant.

System (5) is said to be type-$K$ monotone [12] if whenever $\bar{x}$ and $\bar{y}$ lie in $U$ and if $\bar{x} \preceq_K \bar{y}$ then $x(t, \bar{x}) \preceq_K y(t, \bar{y})$ for all $t \geq 0$ for which both solutions are defined. In this case we say that the flow of (5) preserves the ordering $\preceq_K$.

**Lemma 1 ([12])** If $f \in C^1(U)$ where $U$ is open and convex in $\mathbb{R}^n$, then $x(t, x_0)$ preserves the partial ordering $\preceq_K$ for $t \geq 0$ if and only if $K f(x)K$ has nonnegative off-diagonal elements for every $x \in U$, where $K = \text{diag}\{k_1, \ldots, k_n\}$, $k_i \in \{\pm 1\}$, is the “signature” of the orthant $K$.

If $K = \mathbb{R}^n_+$ then we have the class of cooperative systems. System (5) is said to be cooperative in $U \subset \mathbb{R}^n$ if the differentiable vector field $f : \mathbb{R}^n \to \mathbb{R}^n$ is such that the Jacobian matrix $\frac{\partial f}{\partial x}(x)$ is Metzler for all $x \in U$, that is $\left[\frac{\partial f}{\partial x}(x)\right]_{ij} \geq 0$ for all $i \neq j$.

**III. MULTIPLE EQUILIBRIA IN COLLECTIVE DECISION-MAKING SYSTEMS**

The class of nonlinear systems considered in this work is the following [1], [20]

$$\dot{x} = -\Delta x + \pi A\psi(x)$$

(6)

where $x \in \mathbb{R}^n$, $\pi > 0$ is a scalar parameter, $A = [a_{ij}]$ is the weighted adjacency matrix of the network, $\Delta = \text{diag}\{\delta_1, \ldots, \delta_n\}$, and $\psi(x) = [\psi_1(x_1) \ldots \psi_n(x_n)]^T$. The matrix $A$ is assumed to be nonnegative with null diagonal, irreducible and symmetrizable. A Laplacian-like assumption links $\Delta$ and $A$: $\delta_i = \sum_j a_{ij}$. In the context of agent-based group decisions, $\delta_i$ represents the inertia of the $i$-th agent to the development of an opinion, $\psi_i(x_i)$ the capacity of the $i$-th agent of transmitting its opinion to the other agents, mediated by the pairwise susceptibilities $a_{ij}$. From the irreducibility assumption on $A$ it follows that each $\delta_i$ is strictly positive, $\delta_i > 0$. Denote $\delta_{\text{min}} = \min_i\{\delta_i\}$ and $\delta_{\text{max}} = \max_i\{\delta_i\}$. The parameter $\pi$ represents a community social effort. See [1], [3] for more details.

The vector of functions $\psi(x)$ is such that each $\psi_i(x_i) : \mathbb{R} \to \mathbb{R}$ satisfies the following conditions

$$\psi_i(x_i) = -\psi_i(-x_i), \quad \forall x_i \in \mathbb{R} \quad \text{(odd)}$$

(A.1)

$$\frac{\partial \psi_i}{\partial x_i}(x_i) > 0, \forall x_i \in \mathbb{R} \quad \text{and} \quad \frac{\partial \psi_i}{\partial x_i}(0) = 1 \quad \text{(monotone)}$$

(A.2)

$$\lim_{x_i \to \pm \infty} \psi_i(x_i) = \pm 1 \quad \text{(saturated)}$$

(A.3)

The assumption (A.3) guarantees the boundedness of the solutions, and together with (A.2) allows to exclude the presence of limit cycles. Typical choices for $\psi_i$ are a hyperbolic tangent function, a (modified) Michaelis-Menten function $\psi_i(x_i) = \frac{x_i}{1 + x_i^2}$, $x_i \in \mathbb{R}$ [5], or a (modified) Boltzmann function $\psi_i(x_i) = \frac{1 - e^{-2x_i}}{1 + e^{-2x_i}}, x_i \in \mathbb{R}$ [7]. The versions here proposed satisfy the conditions (A.1)-(A.3).

Additionally, if each nonlinear function $\psi_i(x_i)$ satisfies the following condition

$$\psi_i(x_i) \begin{cases} \text{strictly convex} & \forall x_i < 0 \\
\text{strictly concave} & \forall x_i > 0 
\end{cases} \quad \text{(sigmoidal)}$$

(A.4)

then, from (2) and (A.4), $|\psi_i(x_i)| < |x_i|$ for all $i$ and $x_i \neq 0$. While all the examples mentioned above (hyperbolic tangent, Michaelis-Menten and Boltzmann functions) satisfy also (A.4), nonsigmoidal functions often satisfy (A.1)-(A.3) but not (A.4).

From these assumptions, it follows that the Jacobian matrix of (6), given by $-\Delta + \pi A\frac{\partial \phi}{\partial x}(x)$, is Metzler. Therefore, the system (6) is cooperative.

It is convenient to rewrite the system (6) in the following (“normalized”) form

$$\dot{x} = \Delta [-x + \pi H_1 \psi(x)], \quad x \in \mathbb{R}^n.$$  

(7)

where the matrix $H_1 := \Delta^{-1} A$. Denote also $H := \pi H_1$. Observe that it satisfies some useful properties:

- $H$ is nonnegative and irreducible, so Theorem 2 applies.
- All the rows sums of $H$ are equal to $\pi$, that is $H \mathbb{1}_n = \pi \mathbb{1}_n$.
- It follows that $(\pi, \mathbb{1}_n)$ is the Perron-Frobenius eigenpair of $H$.
- As the matrix $A$ is symmetrizable, also $H$ is symmetrizable, hence it has real eigenvalues.

We will see below that the existence (and the stability) of multiple equilibria is strictly related to the structure of the spectrum of the matrix $H$.

**A. Existence of multiple equilibria: a necessary condition**

Consider the system (7) (or (6)) where each nonlinear function $\psi_i(x_i)$ satisfies the properties (A.1)-(A.4). Let us start by recalling what is known for this system when we
vary the parameter $\pi$. By construction, the origin is always an equilibrium point for (7) (or (6)). When $\pi < 1$, $x = 0$ is the only equilibrium point, it is globally asymptotically stable and locally exponentially stable. This follows from diagonal dominance, and can be easily shown by a Lyapunov argument, see [1], [20], [21]. At $\pi = \pi_1 = 1$ the system undergoes a pitchfork bifurcation, the origin becomes a saddle point and two more equilibria emerge, $x^+ \in \mathbb{R}_{+}^n$ and $x^- \in \mathbb{R}_{-}^n$ [1]. It follows from the analysis of [20] that, for all $\pi > 1$, $x = 0$ is an unstable equilibrium point, while both $x^+$ and $x^-$ are locally asymptotically stable with domain of attraction given by (at least) the entire orthant for any $\pi > 0$. $\mathbb{R}_{+}^n$ (resp. $\mathbb{R}_{-}^n$) are in fact invariant for the system (7). What happens outside these two orthants is however unknown. When $\pi > 1$ and $\pi - 1$ sufficiently small, the behavior of the system (7) outside $\mathbb{R}_{+}^n$ and $\mathbb{R}_{-}^n$ has been discussed in [1]. Only the three equilibrium points mentioned above are possible, two locally stable [20] and the origin as a saddle point. However, when $\pi > 1$ grows, the bifurcation analysis of [1] does not suffice anymore.

Our task is therefore to investigate the behavior of the system (7) when $\pi > 1$ grows and $x \in \mathbb{R}^n$ (case not described by [20] and [1]). In particular, we would like to understand for what interval $(1, \pi_2)$ of the bifurcation parameter $\pi$ extra equilibria not contained in $\mathbb{R}_{+}^n / \mathbb{R}_{-}^n$ cannot appear, and what happens for $\pi > \pi_2$.

The following theorem introduces a necessary condition that has to be verified in order to have an equilibrium point $\bar{x}$ in a generic orthant $K \neq \mathbb{R}_{+}^n, \mathbb{R}_{-}^n$ for the system (7).

**Theorem 4** Consider the system (7) where each nonlinear function $\psi_i(x_i)$ satisfies the properties (A.1)$\div$(A.4). If the system admits an equilibrium point $\bar{x} \in K$, where $K$ is an orthant in $\mathbb{R}^n$ and $K \neq \mathbb{R}_{+}^n, \mathbb{R}_{-}^n$, then $\exists \lambda(H) \in \Lambda(H)$ such that $\lambda(H) > 1$ and $\lambda(H) \neq \rho(H)$.

**Proof.** Let $\bar{x} \in K$ be an equilibrium point for (7). Because $\Delta$ is diagonal and positive definite, from (7) it follows

$$\bar{x} = H\psi(\bar{x}).$$

(8)

First notice that $\bar{x} \in K$ also $\psi(\bar{x}) \in K$, because from (A.1) and (A.2) $\psi_i(x_i)$ keeps the same sign of $x_i$ for all $i = 1, \ldots, n$. Introduce the diagonal matrix $M(\bar{x}) = \text{diag}\{m_1(\bar{x}_1), \ldots, m_n(\bar{x}_n)\}$ where each element is given by

$$m_i(\bar{x}_i) = \frac{\psi_i(\bar{x}_i)}{\bar{x}_i}, \quad i = 1, \ldots, n.$$

Since $\bar{x} > K$, 0, the ratio is well-defined. The dependence of $M(\bar{x})$ from $\bar{x}$ will be omitted from now on. From (A.2) and (A.4) one gets $|\psi_i(x_i)| < |x_i|$ (i.e. $x_i \neq 0$, which leads to $m_i = \frac{\psi_i(x_i)}{x_i} \in (0, 1)$ for all $i$. Then $0 < \text{diag}(M) < \mathbb{I}_n$. Applying the change of coordinates $\bar{z} = M^{1/2}\bar{x}$, from $\psi(\bar{x}) = M\bar{x}$, we get

$$\bar{z} = M^{1/2}H\bar{M}^{1/2}\bar{z}.$$  

(9)

Eq. (9) represents the eigenvalue equation for the matrix $M^{1/2}H\bar{M}^{1/2}$, that is $(1, \bar{z})$ is an eigenpair of $M^{1/2}H\bar{M}^{1/2}$. Furthermore $\bar{z} \in K$ since, for each $i$, $\bar{z}_i = \sqrt{m_i}\bar{x}_i$ and $m_i$ is strictly positive. Observe that $M^{1/2}H\bar{M}^{1/2}$ is nonnegative and irreducible and let its eigenvalues be arranged in a non-decreasing order. Theorem 2 states that $\lambda_n(M^{1/2}H\bar{M}^{1/2}) = \rho(M^{1/2}H\bar{M}^{1/2})$ is real and positive and that its associated eigenvector is real and in the positive orthant of $\mathbb{R}^n$. Then $\rho(M^{1/2}H\bar{M}^{1/2}) > 1$, since the eigenvector associated to 1 is $\bar{z} \in K \neq \mathbb{R}_{+}^n, \mathbb{R}_{-}^n$. To prove that $\exists \lambda(H) \in \Lambda(H)$ such that $\lambda(H) > 1$ we proceed in steps.

- Since the matrix $A$ is symmetrizable, let $A = D_A S_A$, where $D_A$ is a diagonal matrix with positive diagonal entries and $S_A$ is a symmetric matrix. Notice that the matrix $S_A$ is still irreducible, nonnegative and with null diagonal.

- The matrix $H$, which can be written as $H = \pi\Delta^{-1}D_A S_A$, is symmetrizable. Define the matrix $D_H := \pi\Delta^{-1}D_A$, diagonal with positive diagonal entries. Then $S_A = D_H^{-1}H$ is the symmetrization of $H$ while $D_H^{-1}$ is the symmetrizer of $H$.

- Consider the matrix $\tilde{H}$ defined as

$$\tilde{H} := D_H^{-1/2}H D_H^{1/2} = D_H^{1/2}S_A D_H^{-1/2}.$$ 

By construction it is symmetric, nonnegative, irreducible and similar to $H$. Because $H$ and $\tilde{H}$ have the same eigenvalues, it is just necessary to prove that $\exists \lambda(\tilde{H}) \in \Lambda(\tilde{H})$ such that $\lambda(\tilde{H}) > 1$ and $\lambda(\tilde{H}) \neq \rho(H)$.

- The matrices $M^{1/2}H^{1/2}$ and $M^{1/2}\tilde{H}M^{1/2}$ are similar. Indeed

$$M^{1/2}H^{1/2} = D_H^{1/2} \left[ M^{1/2}\tilde{H}M^{1/2} \right] D_H^{-1/2} \sim M^{1/2}\tilde{H}M^{1/2}.$$ 

Then they have the same eigenvalues and in particular, from equation (9), it follows that $(1, D_H^{1/2}\bar{z})$ is an eigenpair of the matrix $M^{1/2}\tilde{H}M^{1/2}$. Since $D_H^{-1/2}\bar{z} \in K$, it follows that $\exists k \neq n$ such that $\lambda_k(M^{1/2}\tilde{H}M^{1/2}) = 1$.

- The matrix $M^{1/2}\tilde{H}M^{1/2}$ is symmetric and $M^{1/2}$ is nonsingular so it is possible to apply Theorem 3. There exists a positive real number $\theta_k$ such that

$$\lambda_k(M^{1/2}\tilde{H}M^{1/2}) = \theta_k \lambda_k(\tilde{H})$$

and

$$\lambda_1 \left( (M^{1/2})^T \right) \leq \theta_k \leq \lambda_n \left( (M^{1/2})^T \right)$$

where $\lambda_1(M) = m_{\text{min}}$ and $\lambda_n(M) = m_{\text{max}}$. Then $\theta_k \leq m_{\text{min}} < 1$. Since $k \neq n$ is the index for which $\lambda_k(M^{1/2}\tilde{H}M^{1/2}) = 1$, it follows

$$1 = \lambda_k(M^{1/2}\tilde{H}M^{1/2}) = \theta_k \lambda_k(\tilde{H}) < \lambda_k(\tilde{H}).$$

Because $k \neq n$, this implies the existence of an eigenvalue $\lambda(\tilde{H}) \in \Lambda(\tilde{H})$ such that $\lambda(\tilde{H}) > 1$ and $\lambda(\tilde{H}) \neq \rho(H)$. Consequently, since $H$ and $\tilde{H}$ are similar, there exists $\lambda(H) \in \Lambda(H)$ such that $\lambda(H) > 1$ and $\lambda(H) \neq \rho(H)$.

When instead of (7) the system (6) is considered, then the results are less sharp, since they depend on the diagonal terms, which are not all identical as in (7).
Corollary 2 Consider the system (6), where each nonlinear function $\psi_i(x_i)$ satisfies the properties (A.1)$\div$(A.4). If the system admits an equilibrium point $\bar{x} \in K$, where $K$ is an orthant in $\mathbb{R}^n$ and $K \neq \mathbb{R}^n$, then $\exists \lambda(A) \in \Lambda(A)$ such that $\lambda(A) > 0$ and $\lambda(\bar{A}) \neq \rho(\bar{A})$ for which $\pi(\lambda(A)) > \delta_{\text{min}}$.

Proof. Let the symmetrizable matrix $A$ be written as $A = DS_A$, where $D$ is a diagonal matrix with positive diagonal entries and $S_A$ is a symmetric matrix. Then $H = \pi \Delta^{-1} DS_A$.

Define a new matrix
$$\tilde{H} := \Delta^{1/2} D^{1/2} \Delta^{-1/2} \Delta^{-1/2} = \Delta^{-1/2} \tilde{A} \Delta^{-1/2}$$
where $\tilde{A}$ is defined as $\tilde{A} := D^{-1/2} AD^{1/2} = D^{1/2} S_A D^{1/2}$.

By construction, $\tilde{H}$ is symmetric, similar to $H$ and congruent to $\tilde{A}$, while $\tilde{A}$ is symmetric, similar to $A$ and congruent to $S_A$. Because $\tilde{H}$ and $\tilde{A}$ are both symmetric, it is possible to apply Theorem 3. To simplify the notation, let $S := \sqrt{\pi} \Delta^{-1/2}$ and $\tilde{H} = \tilde{S} \tilde{S}^T$, and the eigenvalues be arranged in a nondecreasing order. Therefore, there exists a positive real number $\theta_k$ such that the following conditions hold:

$$\lambda_k(\tilde{H}) = \theta_k \lambda_k(\tilde{A}) \quad (10)$$
$$\lambda_1(\tilde{S} \tilde{S}^T) \leq \theta_k \leq \lambda_n(\tilde{S} \tilde{S}^T) \quad (11)$$

From Theorem 4, $\exists k \neq n$ such that $\lambda_k(H) > 1$. It follows, by similarity, that $\lambda_k(\tilde{H}) > 1$. Then the condition (10) where $\theta_k > 0$ and $k \neq n$, yields $\lambda_k(\tilde{A}) > 0$ and $\lambda_k(\tilde{A}) \neq \rho(\tilde{A})$.

Moreover, since $\tilde{S} \tilde{S}^T = \pi \Delta^{-1}$, then
$$\lambda_1(\tilde{S} \tilde{S}^T) = \frac{\pi}{\delta_{\text{max}}}, \quad \lambda_n(\tilde{S} \tilde{S}^T) = \frac{\pi}{\delta_{\text{min}}}.$$  

From (11), (10) and the result of Theorem 4, it follows that
$$1 < \frac{\pi}{\delta_{\text{min}}} \lambda_k(\tilde{A})$$
i.e. $\pi \lambda_k(\tilde{A}) > \delta_{\text{min}}$. But $\tilde{A}$ and $A$ are similar, that is, they have the same eigenvalues. Then $\pi \lambda_k(A) > \delta_{\text{min}}$, which concludes the proof.

Proposition 1 Let $n \leq 3$ and $A \in \mathbb{R}^{n \times n}$ be an irreducible, symmetrizable, nonnegative matrix with null diagonal. Then $A$ cannot have two different real positive eigenvalues.

Proof. The matrix $A$ is symmetrizable which implies that its eigenvalues are real. Let them be arranged in a nondecreasing order, that is $\lambda_n(A) > \lambda_{n-1}(A) \geq \cdots \geq \lambda_1(A)$. It is always true that
$$\sum_{i=1}^n \lambda_i(A) = \text{Tr}(A) = 0, \quad \prod_{i=1}^n \lambda_i(A) = \det(A).$$

Since $A$ is nonnegative and irreducible it is possible to apply Theorem 2 from which it follows that $\lambda_n(A) = \rho(A) > 0$.

Then
- If $n = 2$, $A = \begin{bmatrix} 0 & a_{12} \\ a_{21} & 0 \end{bmatrix}$ and the conditions on its trace and determinant become
  $$\begin{align*}
  \lambda_1(A) + \lambda_2(A) &= 0 \\
  \lambda_1(A)\lambda_2(A) &= -a_{12}a_{21} < 0
  \end{align*}$$
  which yields $\lambda_2(A) < 0$.
- If $n = 3$, $A = \begin{bmatrix} 0 & a_{12} & a_{13} \\ a_{21} & 0 & a_{23} \\ a_{31} & a_{32} & 0 \end{bmatrix}$ and the conditions on its trace and determinant become
  $$\begin{align*}
  \lambda_1(A) + \lambda_2(A) + \lambda_3(A) &= 0 \\
  \lambda_1(A)\lambda_2(A)\lambda_3(A) &= a_{12}a_{23}a_{31} + a_{13}a_{21}a_{32} \geq 0
  \end{align*}$$
  which yields $\lambda_1(A) = -\lambda_3(A) < 0$ and $\lambda_2(A) = 0$ or $\lambda_1(A), \lambda_2(A) < 0$.

B. A geometric necessary and sufficient condition

The following lemma provides a geometric interpretation of the condition of Theorem 4. Consider the Laplacian $L_1 = I - H_1$. Since $\rho(H_1) = 1$, by construction, the least eigenvalue
\( \lambda_1(L_1) = 1 - \rho(H_1) \) is the origin. Recall that the second leftmost eigenvalue of \( L_1 \), \( \lambda_2(L_1) \), is called the algebraic connectivity of \( L_1 \) [24]. If \( \lambda_{n-1}(H_1) \) is the second largest eigenvalue of \( H_1 \), then the algebraic connectivity of \( L_1 \) is \( \lambda_2(L_1) = 1 - \lambda_{n-1}(H_1) \).

**Lemma 2** The range of values of \( \pi \) for which no extra equilibrium of the system (7) (other than 0, \( x^+ \) and \( x^- \)) can appear is given by \((1, \pi_2)\), with \( \pi_2 = \frac{1}{\lambda_{n-1}(H_1)} > 1 \), and hence it is determined by the algebraic connectivity \( \lambda_2(L_1) \).

**Proof.** For (3) it holds that \( \sum_2 h_{1,i} = \rho(H_1) = 1 \forall i \). This means that the Laplacian \( L_1 \) has all identical Geršgorin disks, all centered at 1 and passing through the origin:

\[
\begin{cases}
  s \in \mathbb{C} \text{ s.t. } |s - 1| < \frac{1}{\sum_{i=1}^{n} \frac{d_{ij}}{d_i}} = 1
\end{cases}
\]

From Geršgorin Theorem [28], the eigenvalues of \( L_1 \) are located in the union of the \( n \) disks. The least eigenvalue \( \lambda_1(L_1) = 0 \) lies on the boundary of the Geršgorin disks. The other eigenvalues of \( L_1 \) are strictly inside the disks because of irreducibility and positive semidefiniteness of \( L_1 \). When \( \pi > 1 \), all the eigenvalues of \( H = \pi H_1 \) are increased in modulus, and the Geršgorin disks of \( I - H \) are still all centered in 1 but have radius \( \pi \). The condition of Theorem 4, \( \exists \lambda(H) > 1, \lambda(H) \neq \rho(H) \) corresponds to the existence of \( \pi \) s.t. \( \pi \lambda(H_1) > 1 \) for \( \lambda(H_1) > 0 \) and \( \lambda(H_1) \neq 1 \), i.e., it corresponds to requiring that \( \pi > \pi_2 \), where \( \pi_2 = \frac{1}{\lambda_{n-1}(H_1)} > 1 \). Whenever this happens, \( 1 - \pi \lambda_{n-1}(H_1) \) crosses into the left half of the complex plane.

The insight given by Lemma 2 allows to show that the condition of Theorem 4 is also sufficient. Since we use bifurcation theory and singularity analysis in the proof, we have however to restrict to the case of algebraic connectivity \( \lambda_2(L_1) \) which is a simple eigenvalue (property which is generic for weighted graphs, see [26]).

**Theorem 6** Consider the system (7) where each nonlinear function \( \psi_i(x) \) satisfies the properties (A.1)÷(A.4). Assume further that the second largest eigenvalue of \( H_1 \), \( \lambda_{n-1}(H_1) \) is simple. The system admits an equilibrium point \( \hat{x} \in \mathcal{K} \), where \( \mathcal{K} \) is an orthant in \( \mathbb{R}^n \) and \( \mathcal{K} \neq \mathbb{R}^+_n, \mathbb{R}_n^- \), if and only if \( \pi > \pi_2 = \frac{1}{\lambda_{n-1}(H_1)} > 1 \).

**Proof.** Necessity was proven in Theorem 4. In fact, as shown in Lemma 2, since \( \rho(H_1) = 1 \), the condition of Theorem 4 corresponds to \( \pi > \pi_2 = \frac{1}{\lambda_{n-1}(H_1)} > 1 \). To show that mixed sign equilibria appear exactly at \( \pi = \pi_2 = \frac{1}{\lambda_{n-1}(H_1)} \), we use bifurcation theory, in particular singularity theory and Lyapunov-Schmidt reduction for pitchfork bifurcations [25], see also [1]. Consider

\[
\Phi(x, \pi) = -x + \pi H_1 \psi(x) = 0
\]

Denote \( v_2 \) and \( w_2, w_2^T v_2 = 1 \), the right and left Fiedler vectors, i.e., the eigenvectors relative to \( \lambda_{n-1}(H_1) \). From Theorem 2, \( v_2, w_2 \in \mathcal{K} \) for some \( \mathcal{K} \neq \mathbb{R}_n^+, \mathbb{R}_n^- \). Let \( J = \frac{\partial \Phi}{\partial x}(0, \pi_2) = -I + \pi_2 H_1 \). Observe that range(J) = \( \ker(JT)^\perp = \{\text{span}\{w_2\}\}^\perp \) and that \( \ker(J) = \text{span}\{v_2\} \). Let \( E \) denote the projection of \( \mathbb{R}^n \) onto range(J) = \( \{\text{span}\{w_2\}\}^\perp \), \( E = I - w_2^T w_2 \), and \( I - E \) the projection onto \( \ker(J) = \{\text{span}\{v_2\}\} \). Split \( x \) accordingly: \( x = yv_2 + r \), where \( y \in \mathbb{R} \) and \( r = Ex \in \{\text{span}\{w_2\}\}^\perp \).

Near \( 0, \pi_2 \), (13) can be split into

\[
E\Phi(x, \pi) = E(-x + \pi H_1 \psi(x)) = 0 \tag{14a}
\]

\[
(I - E)\Phi(x, \pi) = (I - E)(-x + \pi H_1 \psi(x)) = 0 \tag{14b}
\]

Since \( \lambda_{n-1}(H_1) \) is simple, at \( \pi = \pi_2 \) (13) has a simple singularity. Hence for (14a) the implicit function theorem applies and it is possible to express \( r = R(yv_2, \pi) \). The explicit expression of \( R(\cdot) \) is not needed in what follows. Replacing \( r \) in (14b), we get the center manifold

\[
\phi(y, \pi) = (I - E)(-yv_2 - R(yv_2, \pi) + \pi H_1 \psi(yv_2 + R(yv_2, \pi))) = 0 \tag{15}
\]

Define \( g(y, \pi) = w_2^T \phi(y, \pi) \), where \( w_2 \in \{\text{range(J)}\}^\perp \). The recognition problem for a pitchfork bifurcation requires to compute at \( 0, \pi_2 \) the partial derivatives \( g_y, g_{yy}, g_{yy}, g_{\pi\pi} \). In this case the calculation is simplified by the fact that \( \Phi(x, \pi) \) is odd in \( x \). For instance, since \( \Phi \) has a singularity at \( 0, \pi_2 \) it follows that the directional derivative along \( v_2 \) vanishes:

\[
\Phi_y(0, \pi_2) = \frac{\partial \Phi}{\partial x}(x, \pi) \bigg|_{(0, \pi_2)} = (-I + \pi H_1 \frac{\partial \psi(x)}{\partial x}) v_2
\]

\[
= (-I + \pi_2 H_1) v_2 = -v_2 + \pi_2 \lambda_{n-1}(H_1) v_2 = 0
\]

where we have used \( \frac{\partial \psi(x)}{\partial x} \bigg|_0 = 1 \). Similarly (see [25])

\[
\Phi_y(0, \pi_2) = \frac{\partial}{\partial \pi} \left( \frac{\partial \Phi}{\partial x}(x, \pi) \bigg|_{(0, \pi_2)} v_2 \right) v_2
\]

\[
= \pi H_1 \frac{\partial^2 \psi(x)}{\partial x^2} v_2 \bigg|_{(0, \pi_2)} = 0
\]

because \( \frac{\partial^2 \psi(x)}{\partial x^2} \bigg|_0 = 0 \), and

\[
\Phi_y(0, \pi_2) = \frac{\partial}{\partial \pi} \left( \frac{\partial \Phi}{\partial x}(x, \pi) \bigg|_{(0, \pi_2)} v_2 \right) v_2
\]

\[
= H_1 \frac{\partial^2 \psi(x)}{\partial x^2} v_2 \bigg|_{(0, \pi_2)} = \lambda_{n-1}(H_1) v_2
\]

and (using a notation similar to [25], (3.16))

\[
\Phi_y(0, \pi_2) = \frac{\partial^3 \Phi}{\partial x^3}(x, \pi) \bigg|_{(0, \pi_2)} (v_2, v_2, v_2)
\]

\[
= \pi_2 H_1 \begin{bmatrix} \beta_1 \\ \cdots \\ \beta_n \end{bmatrix} \begin{bmatrix} v_2^2 \\ \cdots \\ v_2^n \end{bmatrix}
\]

where, from (A.4), \( \beta_i = \frac{\partial \psi(x)}{\partial x^2} \bigg|_0 < 0 \). Consequently, for
the projections along $v_2$: $\phi_y(0, \pi_2) = (I - E)\Phi_y(0, \pi_2) = 0$, and, similarly, $\phi_y(0, \pi_2) = 0$. As for the two nonvanishing partial derivatives: $\phi_y(0, \pi_2) = (I - E)\Phi_y(0, \pi_2) = \lambda_{n-1}(H_1)v_2$ and $\phi_y(0, \pi_2) = (I - E)\Phi_y(0, \pi_2) = \lambda_{n-1}(H_1)v_2$. Therefore $g_y(0, \pi_2) = g_y(0, \pi_2) = g_y(0, \pi_2) = 0$ and $g_y(0, \pi_2) = \lambda_{n-1}(H_1) > 0$, $g_y(0, \pi_2) = \sum_{i=1}^{n} 1_i w_{2,i} v_{2,i} < 0$ since $w_{2,i} v_{2,i} > 0$ $\forall i$, which completes the recognition problem for a pitchfork bifurcation [25]. Hence at $\pi = \pi_2$ the system crosses a second bifurcation through the origin and two new equilibria appear along $\pm \pi_2$. Since $v_2 \in K$, these equilibria must belong to $K$ and $-K$.

Notice that unlike most arguments based on singularity analysis of bifurcations, our result in Theorem 6 is not a local one, as our proof of necessity (Theorem 4) is nonlocal.

When $\lambda_{n-1}(H_1)$ has multiplicity higher than one, then singularity analysis based on the normal form of a pitchfork bifurcation does not apply, although we expect that similar sufficiency results can be obtained through more advanced bifurcation theory.

A pictorial view of the situation described in Theorem 6 will be given below in Example 1, see in particular Fig. 1 and Fig. 2 (a), (b).

If instead we look at system (6), and at the Laplacian $L = \Delta - A$, then, when $\pi = 1$, the Geršgorin disks are centered at $\delta_i$ and have different radii, equal to $\delta_i$. However, this cannot be straightforwardly reformulated in terms of $\rho(A)$, as (4) (instead of (3)) now holds: $\delta_{\min} \leq \rho(A) \leq \delta_{\max}$. When exploring the values $\pi > 1$, then the Geršgorin disks of $L = \Delta - \pi A$ are contained one in the other, according to the corresponding $\delta_i$, and all have nonempty intersection with the left half of $C$, see Fig. 2, panels (c) and (d). In this case, while the eigenvalue condition introduced in Theorem 4 represents the necessary and sufficient condition for the negativity of a second leftmost eigenvalue of $L$, the eigenvalue condition introduced in Corollary 2 is just necessary, due to the presence of the diagonal matrix $\Delta$. Using a similar reasoning it is in fact possible to prove that $\lambda_{n-1}(H) = \pi \theta \lambda_{n-1}(A)$, where the value of the positive constant $\theta$ is not fixed but $\delta_{\min} \leq \theta \leq \delta_{\max}$.

C. Stability properties of multiple equilibria

**Theorem 7** Suppose the system (7) admits an equilibrium point $\bar{x} \in K$, where $K$ is an orthant in $\mathbb{R}^n$ and $K \neq \mathbb{R}^n$, $\mathbb{R}_n^+$. If

$$\pi \max_j \left\{ \frac{\partial \psi_j}{\partial x_j} (\bar{x}) \right\} < 1, \tag{16}$$

then $\bar{x}$ is locally asymptotically stable. Instead, if

$$\pi \min_j \left\{ \frac{\partial \psi_j}{\partial x_j} (\bar{x}) \right\} > 1, \tag{17}$$

then the equilibrium point $\bar{x}$ is unstable.

**Proof.** Let $\bar{x} \in K$ be an equilibrium point for (7). To study the behavior of the dynamical system (7) near the equilibrium point $\bar{x}$, consider the linearization around $\bar{x}$

$$\dot{x} = \Delta \left[ -I + H \frac{\partial \psi}{\partial x} (\bar{x}) \right] (x - \bar{x}). \tag{18}$$

Under the condition (16) it can be proven that the matrix $I - H \frac{\partial \psi}{\partial x}(\bar{x})$ is strictly diagonally dominant, that is $1 > \sum_{j \neq i} h_{ij} \frac{\partial \psi_j}{\partial x_j} (\bar{x}_j)$ for all $i = 1, \ldots, n$. Indeed

$$\sum_{j \neq i} h_{ij} \frac{\partial \psi_j}{\partial x_j} (\bar{x}_j) \leq \max_j \left\{ \frac{\partial \psi_j}{\partial x_j} (\bar{x}_j) \right\} \sum_{j \neq i} h_{ij} = \pi \max_j \left\{ \frac{\partial \psi_j}{\partial x_j} (\bar{x}_j) \right\} < 1.$$

Then it is possible to apply Theorem 1 and state that, under the condition (16), each eigenvalue of the matrix $I - H \frac{\partial \psi}{\partial x}(\bar{x})$ has strictly positive real part. Therefore, each eigenvalue of the matrix $\Delta + (I - H \frac{\partial \psi}{\partial x}(\bar{x}))$ has strictly negative real part, i.e. $\bar{x}$ is locally asymptotically stable.

Now suppose that (17) holds and consider the linearization around $\bar{x}$ (18). Let $\bar{H} := H \frac{\partial \psi}{\partial x}(\bar{x})$ and notice that it is nonnegative and irreducible (therefore it is possible to apply Theorem 2). If the matrix $\bar{H} - I$ admits an eigenvalue with positive real part, it is possible to conclude that the equilibrium point $\bar{x}$ is unstable. For each $i = 1, \ldots, n$, it holds that

$$\sum_{j=1}^{n} \bar{h}_{ij} = \sum_{j=1}^{n} h_{ij} \frac{\partial \psi_j}{\partial x_j} (\bar{x}_j) \geq \min_j \left\{ \frac{\partial \psi_j}{\partial x_j} (\bar{x}_j) \right\} \sum_{j=1}^{n} h_{ij} > \pi > 1,$$

under the hypothesis (17). According to Corollary 1, $\rho(\bar{H}) \geq \min_i (\sum_{j=1}^{n} \bar{h}_{ij})$. From the previous reasoning, it follows that $\rho(\bar{H}) > 1$. Therefore the matrix $\bar{H} - I$ admits a real positive eigenvalue given by $\rho(\bar{H}) - 1$, which implies that the equilibrium point $\bar{x}$ is unstable.

IV. LOCATION OF THE MIXED-SIGN EQUILIBRIA

In this Section we restrict our analysis to the special case of all identical $\psi_j(x_i)$. In this case the equilibrium point in the positive orthant has all identical components as shown in the following lemma.

**Lemma 3** Consider the system (7) where each $\psi_j(x_i)$ satisfies the properties (A.1)÷(A.4) and $\psi_j(\xi) = \psi_j(\xi)$ $\forall i, j$ and $\forall \xi \in \mathbb{R}$. When $\pi > 1$, the positive equilibrium point $x^+ \in \mathbb{R}^n_+$ is such that $\sum_{i} \psi_i(x_i^+) = \frac{1}{\pi}$. Furthermore, $x^+$ is the Perron-Frobenius (right) eigenvector of $H$.

**Proof.** For the matrix $H$ we have that the Perron-Frobenius eigenvalue is $\rho(H) = \pi > 1$ and the corresponding eigenvector is $\mathbb{I}_n$. At $x^+$ it must be $H\psi(x^+) = x^+$. If $\psi(x^+) = \frac{1}{\pi} x^+$ with $x^+ = \alpha \mathbb{I}_n$ for some $\alpha \in (0, 1)$ then we have $H\psi(x^+) = \frac{1}{\pi} \alpha H \mathbb{I}_n = \alpha \mathbb{I}_n$ from which we get the eigenvalue/eigenvector equation $H \mathbb{I}_n = \pi \mathbb{I}_n$. It follows that $x^+ = \alpha \mathbb{I}_n$ is the Perron-Frobenius eigenvector of $H$. The specific value of $\alpha$ depends on the functional form of $\psi_j(x_i)$.

A more important consequence is that for each value of $\pi$ the positive equilibrium point $x^+$ provides an upper bound on the norm that any mixed-sign equilibrium $\bar{x}$ can assume.
Theorem 8 Consider the system (7), where each nonlinear function \( \psi_i(x_i) \) satisfies the properties (A.1)+(A.4) and \( \psi_i(\xi) = \psi_j(\xi) \) \( \forall i, j \) and \( \forall \xi \in \mathbb{R} \). If the system admits an equilibrium point \( \bar{x} \in \mathbb{R}^n \), then \( |\bar{x}| \leq \|x^+\| \).

In order to prove the theorem we use the following lemma.

Lemma 4 Consider the system (7), where each nonlinear function \( \psi_i(x_i) \) satisfies the properties (A.1)+(A.4) and \( \psi_i(\xi) = \psi_j(\xi) \) \( \forall i, j \) and \( \forall \xi \in \mathbb{R} \). If the system admits an equilibrium point \( \bar{x} \in \mathbb{R}^n \), then \( |\bar{x}| \leq \|x^+\| \).

Proof. Introduce the diagonal matrix \( M(\bar{x}) = \text{diag}\{m_1(\bar{x}_1), \ldots, m_n(\bar{x}_n)\} \) as in Theorem 4, where each element is given by \( m_i(\bar{x}_i) = \frac{\psi_i(\bar{x}_i)}{\bar{x}_i}, i = 1, \ldots, n \). Since \( \bar{x} >_K 0 \) the ratio is well-posed. The dependence of \( M(\bar{x}) \) from \( \bar{x} \) will be omitted from now on. Let \( m_{\min} = \min_{1 \leq i \leq n} \left\{ \frac{\psi_i(\bar{x}_i)}{\bar{x}_i} \right\} \) be the index such that \( \frac{\psi_i(\bar{x}_i)}{\bar{x}_i} = m_{\min} \) and suppose without loss of generality that \( \bar{x}_i > 0 \). By definition of \( m_{\min} \) and from (A.2) and (A.4), \( \psi_i(\bar{x}_i) \leq \psi_i(\bar{x}) \) and \( \bar{x}_i \leq \bar{x}_i \) for all \( i \neq l \). At \( \bar{x} \) it must be \( \bar{x} = H\bar{x} \), that is \( \bar{x}_i = \sum_{j \neq i} h_{ij} \psi_j(\bar{x}_j) \) for all \( i = 1, \ldots, n \). This yields

\[
\bar{x}_l = \sum_{j \neq l} h_{ij} \psi_j(\bar{x}_j) \leq \left( \sum_{j \neq l} h_{ij} \right) \psi_{\max}(\bar{x}_i) = \pi \psi_{\max}(\bar{x}_l)
\]

which implies that \( m_{\min} = \frac{\psi_i(\bar{x}_i)}{\bar{x}_i} \geq \frac{1}{\pi} \). Then, since \( m_{\max} \geq m_{\min} \) for all \( i \neq l \), it follows that \( \frac{\psi_i(\bar{x}_i)}{\bar{x}_i} \geq \frac{1}{\pi} \) for all \( i = 1, \ldots, n \).

Proof. [Proof of Theorem 8] Let \( x^+ \in \mathbb{R}^n \) and \( \bar{x} \in \mathbb{R}^n \) be equilibrium points for the system (7). From Lemma 3 and Lemma 4 it follows that \( \frac{\psi_i(\bar{x}_i)}{\bar{x}_i} \geq \frac{1}{\pi} = \frac{\psi_i(x^+_i)}{x^+_i} \) for all \( i = 1, \ldots, n \). This implies that \( |\bar{x}_i| \leq x^+_i \) for each \( i \), which yields \( |\bar{x}| \leq \|x^+\| \).

V. Numerical Analysis

In this Section we first look at the trajectories of a specific numerical example of size \( n = 6 \). Then we perform a computational analysis of the properties of the equilibria for a system of size \( n = 20 \).

Example 1 Consider a network of \( n = 6 \) nodes of weighted adjacency matrix

\[
A = \begin{bmatrix}
0 & 0.1477 & 0 & 0.1698 & 0 & 0.0135 \\
0.4242 & 0 & 0.2626 & 0.3621 & 0 & 0 \\
0 & 0.1889 & 0 & 0 & 0.2502 & 0.4158 \\
0.4036 & 0.2997 & 0 & 0 & 0 & 0 \\
0 & 0 & 0.2427 & 0 & 0 & 0.2513 \\
0.0301 & 0.4474 & 0 & 0.2787 & 0 & 0
\end{bmatrix}
\]

which is irreducible, nonnegative and symmetricizable. Consider the system (6) and (7) and assume that each nonlinear function \( \psi_i(x_i) \) is given by the Boltzmann function \( \psi_i(x_i) = \exp\left(\frac{1}{x_i} - x_i \right) \), which satisfies the assumptions (A.1)+(A.4). The Perron-Frobenius eigenvalue of the matrix \( A \) is \( \rho(A) = 0.706 \) and its second largest positive eigenvalue is \( \lambda_{n-1}(A) = 0.515 \), meaning \( \lambda_{n-1}(H_1) = 0.882 \) or \( \tau_2 = 1.216 \). Hence we have:

1. For \( \pi < 1 \), \( x = 0 \) is the only equilibrium point;
2. For \( \pi \in (1, 1.216) \) the only equilibria are \( \{0, x^+, x^-\} \), with \( x^+ = 0 \) and \( x^- = 0 \), see red curve in Fig. 1 (a);
3. For \( \pi > 1.216 \) unstable equilibria \( x_2 \in \mathbb{R}^n \), \( x_2 = \mathbb{R}^n \), then \( (\bar{x}, x) \) oscillates between 500 and 600 for a broad range of \( \pi \) values, belonging to 500-600 different orthants. As shown in Theorem 8, for each \( \pi \) all of the equilibria have become equilibria rapidly grows. For each value of \( \pi \), \( 10^4 \) different initial conditions were tested (we used the fsolve function of Matlab to compute equilibria). The number of equilibria found in this way oscillated between 500 and 600 for a broad range of \( \pi \) values, belonging to 500-600 different orthants. As shown in Theorem 8, for each \( \pi \) all of the equilibria have
a norm which is less than the norm of the corresponding positive/negative equilibrium, see Fig. 3(b), where the ratio \( \frac{||x^+||}{||x^-||} \) is shown. These equilibria were tested for local stability. As shown in panel (c), most but not all of them are unstable, with up to 7 unstable eigenvalues in the Jacobian linearization. It is also remarkable that all stable equilibria tend to have high norm \( ||x|| \), i.e., they tend to be near the boundary of the ball of radius \( ||x^+|| \) to which they have to belong, see Fig. 3(c).

Notice from Fig. 3(b) and (c) that equilibria of small norm \( x \bar{x} \) when interpreted in terms of collective decision-making of agent systems, our results can be recapitulated as follows:

- For a low value of the social effort parameter \( \pi \) (i.e., for \( \pi < 1 \)), the agents are not committed enough to reach an agreement;
- For values of \( \pi \) between 1 and \( \frac{1}{\lambda_{n-2}(H_1)} \), the agents have the right dose of commitment to achieve an agreement among two alternative options \( x^+ \), \( x^- \);
- For values of \( \pi \) bigger than \( \frac{1}{\lambda_{n-1}(H_1)} \), the agents start to become overcommitted, which can lead to other possible decisions, depending on the initial conditions of the system. All these extra decisions represent disagreement situations, i.e., they do not belong to \( \mathbb{R}^n_+ \) or \( \mathbb{R}^n_- \).

Future work includes gaining a better understanding of the bifurcation pattern for \( \pi > \frac{1}{\lambda_{n-1}(H_1)} \), and in presence of “informed agents” in the sense of [1]. It is well-known that the algebraic connectivity is strongly influenced by the topology of the network [23]. We expect that similar arguments apply tamquam to \( \lambda_{n-1}(H_1) \). What remains to be checked is whether these topological considerations are applicable to concrete examples of collective decision-making.

VI. Final Considerations and Conclusions

In this work we have investigated the presence of fixed points for a particular class of nonlinear interconnected cooperative systems, where the nonlinearities are (strictly) monotonically increasing and saturated. We have proposed necessary and sufficient conditions on the spectrum of the adjacency matrix of the network which are required for the existence of multiple equilibria not contained in \( \mathbb{R}^n_+ / \mathbb{R}^n_- \) when the nonlinearities assume both sigmoidal and nonsigmoidal shapes. The stability properties of these equilibria have also been investigated. Although we cannot analytically quantify the number of such equilibria, we can locate them in the solid disk whose radius is given by the norm of the positive equilibrium \( x^+ \).

When interpreted in terms of collective decision-making of agent systems, our results can be recapitulated as follows:

- For a low value of the social effort parameter \( \pi \) (i.e., for \( \pi < 1 \)), the agents are not committed enough to reach an agreement;
- For values of \( \pi \) between 1 and \( \frac{1}{\lambda_{n-2}(H_1)} \), the agents have the right dose of commitment to achieve an agreement among two alternative options \( x^+ \), \( x^- \);
- For values of \( \pi \) bigger than \( \frac{1}{\lambda_{n-1}(H_1)} \), the agents start to become overcommitted, which can lead to other possible decisions, depending on the initial conditions of the system. All these extra decisions represent disagreement situations, i.e., they do not belong to \( \mathbb{R}^n_+ \) or \( \mathbb{R}^n_- \).

Future work includes gaining a better understanding of the bifurcation pattern for \( \pi > \frac{1}{\lambda_{n-1}(H_1)} \), and in presence of “informed agents” in the sense of [1]. It is well-known that the algebraic connectivity is strongly influenced by the topology of the network [23]. We expect that similar arguments apply tamquam to \( \lambda_{n-1}(H_1) \). What remains to be checked is whether these topological considerations are applicable to concrete examples of collective decision-making.
Figure 3: Example 2. Equilibria for a system (7) of size $n = 20$. (a): N. of equilibria (black) found on $10^4$ trials for 500 different values of $\pi$, and n. of orthants to which these equilibria belong (red). (b): norm ratio $\frac{\|\vec{x}\|}{\|\bar{x}^+\|}$ of the equilibria $\bar{x}$ with respect to the corresponding value of $x^+$, as $\pi$ changes. (c): Distribution of the equilibria according to the norm ratio $\frac{\|\bar{x}\|}{\|\bar{x}^+\|}$ (radial distance from origin), to the number of positive eigenvalues of the Jacobian linearization (colormap), and to the n. of components of negative sign (radial angle). Black squares on the unit disk are $x^+$ and $x^-$.
